(Dated: February 2, 2008)

An efficient real space method is derived for the evaluation of the Madelung's potential of ionic crystals. The proposed method is an extension of the Evjen's method. It takes advantage of a general analysis for the potential convergence in real space. Indeed, we show that the series convergence is exponential as a function of the number of annulled multipolar momenta in the unit cell. The method proposed in this work reaches such an exponential convergence rate. Its efficiency is comparable to the Ewald's method, however unlike the latter, it uses only simple algebraic functions.

PACS numbers:

I. INTRODUCTION

Since 90 years a number of methods have been proposed to calculate the electrostatic potential in ionic crystals. These methods can be separated into two categories, the direct summation methods and the indirect summation ones. The former uses a real space summation of the electrostatic potential generated by the ions within a finite volume ($\mathcal{E}$). However, when enlarging the volume $\mathcal{E}$, such partial summations are conditionally convergent. The convergence depends on the specific shape of $\mathcal{E}$. In addition, when achieved, the convergence is quite slow. The indirect summation methods do not present these drawbacks since the long range part of the potential is calculated in the reciprocal space. Indeed, the summation is divided into two parts, a short range one, evaluated by a direct summation in real space and a long range one evaluated in the reciprocal space. Among these methods, the most widely used is the Ewald's method[1], which is actually considered as the reference for Madelung potential calculations.

Despite its quality the Ewald's method is not easily usable in different domains of physics. This is for instance the case in clusters ab-initio calculations used for the treatment of strongly correlated systems, the study of diluted defects in materials or adsorbates or for QM/MM type of calculations. For this types of calculations, real space direct summation methods are used. There is thus a need for efficient and accurate techniques for the determination of the Madelung potential in real space.

The convergence problems found in real space summation are linked to the shape of the summation volume, $\mathcal{E}$, and more specifically the charges at its surface. In order to insure the convergence of the summation, the surface charges are renormalized. Several methods have been proposed for this purpose.

The most common and simple one is the Evjen's method[2]. This method uses a volume $\mathcal{E}$, built from a finite number of crystal unit cells, and renormalizes the surface charges by a factor 1/2, 1/4 or 1/8 according whether the charge belong to a face, edge or corner of $\mathcal{E}$. This method insures, in most cases, the convergence of the electrostatic potential when $\mathcal{E}$ increases. However, in some cases such as the famous CsCl it does not converge to the proper value.[2]

Other authors[3,4] proposed to renormalize not only the surface charges, but also the charges included in a thin skin volume. The adjustment of the renormalization factors are, in this case, numerically determined so that to reproduce the exact potential, previously computed using the Ewald's method at a chosen set of positions. Such a method presents the advantage of reaching a very good precision. However several drawbacks can be pointed out : i) the previous calculation of the electrostatic potential using the Ewald's method at a large number of space positions, ii) the necessity to invert a large linear system to determine the renormalization factors and iii) finally the fact that the latter are not chosen on physical criteria. Indeed, this last point induces the possibility that the renormalization factors can be either larger than one or negative. It results that even if the electrostatic potential is very accurate at the chosen reference positions, its spatial variations can be unphysical and thus, the precision can strongly vary when leaving the reference points.

Marathe *et al*[5] suggested a physical criterion, based on the analysis of the convergence of the real space summation, for the choice of the renormalization factors. Indeed, it is known that the direct space summation converges to the proper limit if the volume $\mathcal{E}$ presents null dipole and quadrupole momenta[6,7]. The authors of reference 5 showed, on the simple example of a linear alternated chain, that it is possible to find a finite number of charge renormalization factors allowing the cancellation of these two multipolar momenta. They also assert that the cancellation of additional multipolar momenta increases the speed of convergence. Unfortunately they did not prove this affirmation and more importantly, they did not proposed a practical way to determine the renormalization factors in order to reach this goal.

In the present paper we propose a systematic method for the determination of the renormalization factors allowing the cancellation of a given number of multipolar momenta as well as a careful analysis of the direct

space summation convergence as a function of the number of canceled multipolar momenta. The next section will present the convergence proof, section 3 will develop the method for determination of the renormalization factors and section 4 will present the optimization of the method and illustration on a typical example.

II. CONVERGENCE ANALYSIS

A. Potential at a point

As already mentioned in the introduction, several papers already exist on this subject. However the results are only partial and there is not complete analysis of the convergence issue. We will thus present in this section a global analysis of the electrostatic potential convergence in a real space approach and an estimation of the error.

We want to evaluate the limit of the following series

$$V(\vec{r}_0) = \lim_{n\to\infty} V_n(\vec{r}_0) = \lim_{n\to\infty} \sum_{\vec{R}\in\mathcal{E}_n} \sum_{j\in\mathcal{C}} \frac{q_j}{|\vec{R}+\vec{r}_j-\vec{r}_0|} \quad (1)$$

where $\vec{R}$ is a vector of the Bravais's lattice, j refers to a charge q_j located at the position $\vec{r}_j$ of the unit cell $\mathcal{C}$. $\{\mathcal{E}_n, n\in\mathbb{N}\}$ is a set of volumes such that

$$\lim_{n\to\infty} \mathcal{E}_n = \mathbb{R}^3 \qquad \text{and} \qquad \vec{r}_0 \in \mathcal{E}_0 \quad (2)$$

For the sake of simplicity we require that the set of $\mathcal{E}_n$ also presents the following conditions

$$\mathcal{E}_0 \subset \mathcal{E}_1 \subset \mathcal{E}_2 \subset \cdots \subset \mathcal{E}_n \quad (3)$$

and

$$\text{if } \vec{R}\in\mathcal{E}_n \text{ then } -\vec{R}\in\mathcal{E}_n \quad (4)$$

The well known problem of this series is that the limit depends on the particular choice of the unit cell $\mathcal{C}$ and of the volumes $\mathcal{E}_n$. However, it has been demonstrated that this conditional convergence disappears if one considers a unit cell with zero dipolar and quadrupolar momenta[7]. We will consider in the following that the cell $\mathcal{C}$ fulfills this condition.

The error $\Delta V_n(\vec{r}_0)$ on the electrostatic potential evaluation, $V_n(\vec{r}_0)$, can be written as

$$\Delta V_n(\vec{r}_0) = \sum_{\vec{R}\notin\mathcal{E}_n} \sum_{j\in\mathcal{C}} \frac{q_j}{|\vec{R}+\vec{r}_j-\vec{r}_0|} \quad (5)$$

For large values of n, $\Delta V_n(\vec{r}_0)$ can be evaluated by a multipolar expansion. For practical reasons, we will use an expansion expressed in spherical coordinates. Indeed, for a given order, this expansion contains less terms than the usual multipolar expansion based on Cartesian coordinates. The use of the later multipolar expansion is still possible but is more complex (see ref.8). In spherical coordinates, the multipolar expansion of the error made on $V_n(\vec{r}_0)$ reads[9] :

$$\Delta V_n(\vec{r}_0) = \sum_{\vec{R}\notin\mathcal{E}_n} \sum_{l} \sum_{m=-l}^{l} \mathcal{M}_{lm}(\vec{r}_0) \frac{Y_l^m(\theta,\phi)}{R^{l+1}} \quad (6)$$

where $\mathcal{M}_{lm}(\vec{r}_0)$ are the multipolar momenta of unit cell $\mathcal{C}$ at $\vec{r}_0$. They can be expressed as

$$\mathcal{M}_{lm}(\vec{r}_0) = \sum_{j\in\mathcal{C}} q_j |\vec{r}_j-\vec{r}_0|^l Y_l^{-m}(\theta_j,\phi_j) \quad (7)$$

(R,θ,ϕ) are the spherical coordinates of the Bravais's vector $\vec{R}$ and (ρ_j,θ_j,ϕ_j) the spherical coordinates of $\vec{r}_j-\vec{r}_0$. The Y_l^{-m} are Schmidt semi-normalized spherical harmonics :

$$Y_l^{-m}(\theta_j,\phi_j) = \sqrt{\frac{(l-m)!}{(l+m)!}} P_l^m(\cos\theta) e^{im\phi} \quad (8)$$

where P_l^m are Legendre functions.

In order to overvalue the error, one needs to overvalue the spherical harmonics. We thus consider the addition formula :

$$\sum_{m=-l}^{l} Y_l^m(\theta,\phi)\, Y_l^{-m}(\theta',\phi') = P_l(\cos\gamma) \quad (9)$$

where P_l is a Legendre Polynomial and γ is the angle between (R,θ,ϕ) and (R',θ',ϕ'). It comes for $\theta=\theta'$ and $\phi=\phi'$

$$\sum_{m=-l}^{l} |Y_l^m(\theta,\phi)|^2 = P_l(1) = 1 \quad (10)$$

and thus

$$|Y_l^m(\theta,\phi)| < 1 \quad (11)$$

Using this result, one obtains the following overvalue for the momenta :

$$|\mathcal{M}_{lm}| < Q(r_0+a)^l \quad (12)$$

where a is the typical size of $\mathcal{C}$ (i.e. the diameter of the circumsphere of $\mathcal{C}$) and Q is the sum of the absolute values of its charges

$$Q = \sum_{j\in\mathcal{C}} |q_j| \quad (13)$$

One should notice at this point that $Y_l^m(\theta,\phi)$ has the same parity as l. The contributions of $\vec{R}$ and $-\vec{R}$ unit cells to $\Delta V_n(\vec{r}_0)$ thus cancel when l is odd. Using equations 11 and 12, one gets the following overvaluation :

$$|\Delta V_n(\vec{r}_0)| < Q \sum_{k=p}^{\infty} (4k+1)(r_0+a)^{2k} \sum_{\vec{R}\notin\mathcal{E}_n} \frac{1}{R^{2k+1}} \quad (14)$$

where $2p$ is the order of the first even, non-zero momentum.

Let us now overvalue the sum over the $1/R$ powers by a volume integral. For each cell $\mathcal{C}(\vec{R})$ located at $\vec{R}$, the norm of the position vectors $\vec{r}$ belonging to the volume $\mathcal{C}(\vec{R})$ is smaller than $R+a$. One can thus overvalue $1/R^{2k+1}$ by

$$\iiint_{\mathcal{C}(\vec{R})} \frac{1}{(r-a)^{2k+1}} \frac{dv}{\omega} \tag{15}$$

ω being the volume of the unit cell $\mathcal{C}$. If $\mathcal{R}_n$ is the radius of the insphere of $\mathcal{E}_n$, it comes

$$\begin{aligned} \sum_{\vec{R}\notin\mathcal{E}_n} \frac{1}{R^{2k+1}} &< \iiint_{r>\mathcal{R}_n} \frac{1}{(r-a)^{2k+1}} \frac{dv}{\omega} \\ &< \frac{4\pi}{\omega} \frac{1}{2k-2} \frac{\mathcal{R}_n^2}{(\mathcal{R}_n-a)^{2k}} \end{aligned} \tag{16}$$

and

$$|\Delta V_n(\vec{r}_0)| < \frac{4\pi Q}{\omega} \sum_{k=p}^{\infty} \frac{4k+1}{2k-2} \mathcal{R}_n^2 \left(\frac{r_0+a}{\mathcal{R}_n-a}\right)^{2k} \tag{17}$$

The later sum converges for $\mathcal{R}_n$ large enough, i.e. for $\mathcal{R}_n > r_0+2a$. The decreasing function $(4k+1)/(2k-2)$ can be overvalued by its value in $k=p$. Further summation over k leads to the following expression

$$|\Delta V_n(\vec{r}_0)| < a_p \frac{\mathcal{R}_n^2 (r_0+a)^{2p}}{(\mathcal{R}_n-r_0-2a)(\mathcal{R}_n-a)^{2p-1}} \tag{18}$$

with

$$a_p = \frac{4\pi Q}{\omega} \times \frac{4p+1}{2p-2} \tag{19}$$

The electrostatic potential at $\vec{r}_0$ thus converges as $1/\mathcal{R}_n^{l-2}$ where l is the first, even, non-zero momentum of the unit cell $\mathcal{C}$.

B. Difference of potential between two points

In several applications, as for instance in cluster ab initio calculation, the problem depends on the spatial variations of the potential and not on its absolute value. In such cases it is sufficient to cancel the dipolar momentum of the unit cell in order to ensure the convergence of the calculation. The convergence rate can also be expected to be faster than for the calculation of the potential at a point as we will show in this section.

Let us overvalue the error made on the calculation of a difference of potential between two points located at $\vec{r}_o+\vec{r}_1$ and $\vec{r}_o-\vec{r}_1$:

$$\begin{aligned} \Delta V_n(\vec{r}_0,\vec{r}_1) &= \sum_{\vec{R}\notin\mathcal{E}_n} \sum_{j\in\mathcal{C}} \frac{q_j}{|\vec{R}+\vec{r}_j-\vec{r}_0-\vec{r}_1|} - \frac{q_j}{|\vec{R}+\vec{r}_j-\vec{r}_0+\vec{r}_1|} \\ &= \sum_{\vec{R}\notin\mathcal{E}_n} \sum_{L} \sum_{M=-L}^{L} \mathcal{M}_{LM}(\vec{r}_0) \left(\frac{Y_L^M(\theta_-,\phi_-)}{R_-^{l+1}} - \frac{Y_L^M(\theta_+,\phi_+)}{R_+^{l+1}}\right) \end{aligned} \tag{20}$$

where (R_-,θ_-,ϕ_-) and (R_+,θ_+,ϕ_+) are the spherical coordinates of $\vec{R}-\vec{r}_1$ and $\vec{R}+\vec{r}_1$ respectively. As in the preceding section (R,θ,ϕ) will be the spherical coordinates of $\vec{R}$ and (r_1,θ_1,ϕ_1) those of $\vec{r}_1$.

In order to express the previous expression as a function of $1/R$, we use following expansion of solid spherical harmonics (for simple derivation see ref. 10, see also ref. 11,12) :

$$\begin{aligned} \frac{P_L^M(\cos\theta_-)\, e^{iM\phi_\pm}}{R_-^{L+1}} &= \sum_{n=0}^{\infty} \frac{r_1^n}{R^{L+n+1}} \sum_m \binom{L+n-m}{L-M} \\ &\times (-1)^{M-m} P_{L+n}^m(\cos\theta)\, e^{im\phi} \\ &\times P_n^{M-m}(\cos\theta_1)\, e^{i(M-m)\phi_1} \end{aligned} \tag{21}$$

where the sum over m spans all integer values. Nevertheless, only a finite number of terms will contribute, since $P_l^m = 0$ if $|m|>l$. Setting $l=L+n$ and introducing spherical harmonics leads to :

$$\begin{aligned} \frac{Y_L^M(\theta_-,\phi_-)}{R_-^{L+1}} &= \sum_{l=L}^{\infty} \sum_m \frac{Y_l^m(\theta,\phi)}{R^{l+1}} \\ &\times (-1)^{M-m} \left[\binom{l-m}{L-M}\binom{l+m}{L+M}\right]^{\frac{1}{2}} \\ &\times r_1^{l-L}\, Y_{l-L}^{M-m}(\theta_1,\phi_1) \end{aligned} \tag{22}$$

Considering $\vec{R}_+$ in this equation instead of $\vec{R}_-$ is equivalent to the transformation

$$\begin{aligned} \theta_1 &\longrightarrow \pi-\theta_1 \\ \phi_1 &\longrightarrow \pi+\phi_1 \end{aligned}$$

that results in an overall $(-1)^{l-L}$ factor. Inserting relation 22 into eq. 20 and inverting the summation over l

and L leads to the expansion :

$$\Delta V_n(\vec{r}_0,\vec{r}_1) = \sum_{\vec{R}\notin\mathcal{E}_n}\sum_{l=0}^{\infty}\sum_{m=-l}^{l}\frac{Y_l^m(\theta,\phi)}{R^{l+1}}A_{lm} \qquad (23)$$

with :

$$\begin{aligned} A_{lm} &= \sum_{L=0}^{l}\sum_{M=-L}^{L}\mathcal{M}_{LM}(\vec{r}_0)\left[\binom{l-m}{L-M}\binom{l+m}{L+M}\right]^{\frac{1}{2}} \\ &\times(-1)^{M-m}\, r_1^{l-L}\, Y_{l-L}^{M-m}(\theta_1,\phi_1) \\ &\times\left(1-(-1)^{l-L}\right) \end{aligned} \qquad (24)$$

Considering the parity of Y_{lm}, one can see from eq. 23 that the contributions from cells located at $\vec{R}$ and $-\vec{R}$ cancel when l is odd. Moreover, due to the last term of eq. 24, the A_{lm} coefficients are zero when $l-L$ is even. Only terms with l even and L odd have a non zero contribution, thus only momenta $\mathcal{M}_{LM}(\vec{r}_0)$ with odd order will contribute to the error. The consequence is that the first non-zero contribution in equation 23 corresponds to $l=2p+2$ where $2p+1$ is the first, non-zero, odd momentum of the unit cell.

Let us now find an overvalue of the A_{lm} terms. It is easy to show using a recurrence relation on the values of m and M, that if $|m|\leq l$, $|M|\leq L$ and $|M-m|\leq l-L$, the following relation holds :

$$\binom{l-m}{L-M}\binom{l+m}{L+M}\leq\binom{l}{L}^2 \qquad (25)$$

Using the previous overvaluation of the momenta (eq. 12) one obtains :

$$\begin{aligned} |A_{lm}| &\leq 2Q\sum_{L=0}^{l}(2L+1)\binom{l}{L}(r_0+a)^L r_1^{l-L} \\ &\leq 2Q(2l+1)(r_0+a+r_1)^l \end{aligned} \qquad (26)$$

As in previous section, the sum over $\mathcal{R}$ can be overvalued by a volume integral (cf. eq 16). Overvaluation of the error thus reads :

$$|\Delta V_n(\vec{r}_0,\vec{r}_1)|\leq\sum_{k=p+1}^{\infty}\frac{8\pi Q(4k+1)^2\,\mathcal{R}_n^2}{\omega(2k-2)}\left(\frac{r_0+a+r_1}{\mathcal{R}_n-a}\right)^{2k} \qquad (27)$$

The sum over k converges if $\mathcal{R}_n$ is larger than r_0+2a+r_1. It can be calculated using derivative of power series. After simplification, one obtains :

$$|\Delta V_n(\vec{r}_0,\vec{r}_1)|\leq b_p\frac{\mathcal{R}_n^2(r_0+a+r_1)^{2p+2}}{(\mathcal{R}_n-r_0-2a-r_1)^2(\mathcal{R}_n-a)^{2p}} \qquad (28)$$

where

$$b_p=\frac{8\pi Q}{\omega}\times\frac{16p^2+40p+25}{2p} \qquad (29)$$

As one increase the size of the set of charges, the difference of electrostatic potential between two points converges like $1/\mathcal{R}_n^{l-1}$, where l is now the first, odd, non-zero momentum of the unit cell $\mathcal{C}$. This convergence is slightly faster than the convergence of the absolute value of potential. When the order of the first non zero momentum is even, the convergence rates differ by a factor $1/R^2$, otherwise they are similar.

III. PARTIAL CHARGES

As depicted in the previous section, convergence can be considerably increased if one cancels several multipolar momenta of the unit cell. In general the Evjen method allows to only cancel the dipolar momentum, and thus provides a convergence of the potential differences in $1/\mathcal{R}_n^2$. In order to really take advantage of the former property, one needs a method allowing the cancellation of several multipolar momenta.

In this section we will establish a method to construct unit cells with a chosen number of zero multipolar momenta. The method, based on the usage of partial charges, is general and can be applied to any Bravais's crystal.

Let $(\vec{a}_0,\vec{b}_0,\vec{c}_0)$ be the lattice vectors of the Bravais's crystal, and $\mathcal{C}_0$ the associated unit cell. In order to introduce partial charges, we consider a larger cell $\mathcal{C}_l$ of dimensions $(l\times a_0, l\times b_0, l\times c_0)$, that we will refer as the "*construction cell*". The construction cell thus contains l^3 original unit cells $\mathcal{C}_0$ which positions in $\mathcal{C}_l$ can be labeled by p, q and r indices, ranging from 1 to l.

If we note n_c the number of charges q_i in the original cell $\mathcal{C}_0$, the cell $\mathcal{C}_l$ now contains $n_c\times l^3$ charges. These charges will be corrected by a factor λ_{pqr}^i (where i refers to the charge q_i). When on rebuild the lattice using the construction cells $\mathcal{C}_l$, the cells overlap, and the final charge at position $\vec{r}_i$ corresponds to the superposition of partial charges from several construction cells. It is straightforward to show that the condition to retrieve the nominal value of the charges q_i reads :

$$\sum_{p,q,r=1}^{l}\lambda_{pqr}^i=1 \qquad (1\leq i\leq n_c \qquad (30)$$

At this stage, considering the latter n_c equations, the cell $\mathcal{C}_l$ contains $n_c(l^3-1)$ free parameters that could be used to cancel multipolar momenta. For the sake of simplicity and generality (i.e. for the method not to depend on the particularity of a given crystal), we will impose further conditions on the λ_{pqr}^i coefficients.

We first reduce the problem to a one dimensional problem by setting :

$$\lambda_{pqr}^i=\lambda_p^{a,i}\,\lambda_q^{b,i}\,\lambda_r^{c,i} \qquad (31)$$

where the three coefficients $\lambda_p^{a,i}$, $\lambda_q^{b,i}$ and $\lambda_r^{c,i}$ are used to cancel multipolar momenta of the $1D$ problems obtained

when the cell $\mathcal{C}_0$ is respectively projected on the three axes of the crystal. For each one dimensional problem, the construction cell contains l projected unit cells. The condition on the coefficients now reads :

$$\sum_{p=1}^{l} \lambda_p^{\omega,i} = 1 \qquad (\omega = a, b, c) \tag{32}$$

It is easy to show that, if these coefficients cancel a fixed number of multipolar momenta in each one dimensional problems, the λ^i_{pqr} coefficients will cancel the momenta of same order in the original three dimensional problem.

We further impose to the coefficients to only depend on the fractional coordinates $(\alpha_i, \beta_i, \gamma_i)$ of the charges q_i, in the corresponding direction:

$$\lambda^i_{pqr} = \lambda_p(\alpha_i)\, \lambda_q(\beta_i)\, \lambda_r(\gamma_i) \tag{33}$$

The $\lambda_p(x)$ functions are thus the same for the three directions and for all charges. As a consequence their expression is the same for all crystals. For a given value of x, and considering the condition for the reconstruction of the crystal (eq. 32), we are left with $l-1$ degrees of freedom. We thus impose to the $\lambda_p(x)$ functions to cancel $l-1$ multipolar momenta. This can be done by setting the momenta created at the center of the construction cell by a unique charge q :

$$q\, u_0^k \sum_{p=1}^{l} \lambda_p(x) \left(x + p - 1 - \frac{l}{2}\right)^k = q\, u_0^k\, m_{l,k} \qquad (0 \le k \le l-1) \tag{34}$$

where $u_0 = a_0, b_0,$ or c_0, x is the fractional coordinate of the charge and $m_{l,k}$ are constant values (independant of the crystal specifications). The equation obtained for $k = 0$ corresponds to the condition for the reconstruction of the crystal ($m_{l,0} \equiv 1$). The momenta of the construction cell, can thus be obtained by summing the contributions of all charges. As the unit cell is neutral, these contributions cancel out.

The equations 33 and 34 thus define sets of partial charges that allow to construct cells with $l-1$ zero multipolar momenta. The shape of these partial charges depends on the choice of the $m_{l,k}$ constants values. In order to find the most reasonable choice of partial charges, we search for $m_{l,k}$ constants that satisfy the following physical conditions :

1. $\forall p,\ \lambda_p(x) \in [0, 1]$.
2. The partial charges vary continuously, i.e. $\forall p,\ \lambda_p(x)$ are continuous and $\lambda_p(1) = \lambda_{p+1}(0)$.
3. $\forall p,\ \lambda_p(x)$ decreases monotonously when moving away from the center of the construction cell.
4. The values of the $m_{l,k}$ are as small as possible.

The latter condition ensures that the partial charges are larger in the center of the construction cell and smaller on its edges, and hence that this cell is close to the original one.

We did not find a way to derive the solution of this problem in a general way, for any value of l. We thus determined the solution for fixed values of l up to $l = 6$. In all these cases the first λ_p function presents the same shape :

$$\lambda_1(x) = \frac{x^{l-1}}{(l-1)!} \tag{35}$$

We reasonably assume that this expression is valid for any value of l. As we will see, it is possible to show, a posteriori, that the λ_p functions fulfill the first three conditions.

We will now determine the function λ_p for any l, using the above expression of λ_1 and relation 34. In equation 34, the $m_{k,i}$ constants can be replaced by the value of the momenta obtained for $x = 0$:

$$\sum_{p=1}^{l} \lambda_p(x) \left(x + p - 1 - \frac{l}{2}\right)^k = \sum_{p=1}^{l} \lambda_p(0) \left(p - 1 - \frac{l}{2}\right)^k \tag{36}$$

with $0 \le k \le l-1$. The matrix of this linear system is the transpose of a Vandermonde Matrix. Inversion of the system leads to :

$$\lambda_p(x) = \sum_{q=1}^{l} \lambda_q(0) \prod_{i=1, i\neq p}^{l} \frac{x + i - q}{i - p} \tag{37}$$

The $\lambda_p(0)$ coefficients can now be obtained from the expression of λ_1. Let us consider the latter equation evaluated for $p = 1$, and for l integer values of x :

$$\lambda_1(j) = \sum_{q=1}^{l} \lambda_q(0) \binom{l + j - q}{j - q + 1} \qquad (1 \le j \le l) \tag{38}$$

Replacing $\lambda_1(n)$ by its expression and inverting this linear system leads to the expression of $\lambda_q(0)$ coefficients :

$$\lambda_q(0) = \sum_{j=1}^{q-1} (-1)^j \binom{l}{j} \frac{(q - j - 1)^{l-1}}{(l-1)!} \tag{39}$$

Finally, using eq. 37 and 39 one obtains the expression of the $\lambda_p(x)$ which are polynomial functions of order $l-1$ in x (see fig. 1) :

$$\lambda_p(x) = \sum_{q=1}^{l} \sum_{j=1}^{q-1} (-1)^j \binom{l}{j} \frac{(q - j - 1)^{l-1}}{(l-1)!} \prod_{i=1, i\neq p}^{l} \frac{x + i - q}{i - p} \tag{40}$$

These functions are segments of the uniform sum distribution , i.e. the distribution $P_l(x)$ of the sum of l uniform variates on the interval $[0, 1]$:

$$\lambda_p(x) = P_l(x + p - 1) \qquad (0 \le x \le 1 \text{ and } 1 \le p \le l-1) \tag{41}$$

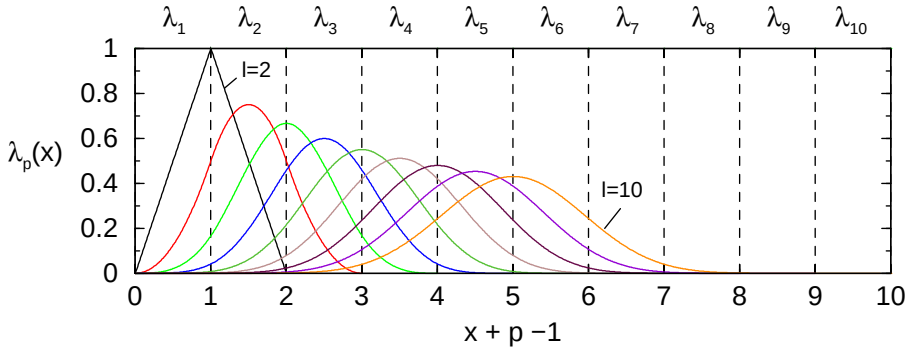

FIG. 1: (color online) $\lambda_p(x)$ functions obtained for values of l ranging between 2 and 10. Intervals correspond to cells $\mathcal{C}_0$ that compose the construction cell $\mathcal{C}_l$. In each intervals, fractional coordinates x range between 0 and 1.

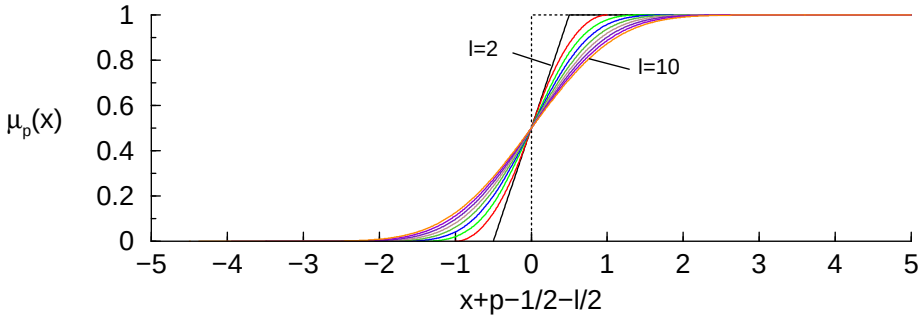

FIG. 2: (color online) Renormalization of the charges at the "left" edge of a crystal fragment, obtained for values of l ranging between 2 and 10. The origin of the abscises corresponds to the position of the edge obtained when using the original cell $\mathcal{C}_0$ (dotted line).

From this relation, it is obvious that the $\lambda_p(x)$ functions satisfy the first three conditions mentioned above.

We now consider a fragment of crystal made of n construction cells $\mathcal{C}_l$. As these cells are composed of l original cells $\mathcal{C}_0$, they partially overlap, and the size of the fragment corresponds to $n+l-1$ cells $\mathcal{C}_0$. $n' = n-l+1$ cells $\mathcal{C}_0$ in the center contains charges with the nominal values q_i, and $l-1$ cells $\mathcal{C}_0$ on each side of the fragment contains partial charges. The latter partial charges are proportional to the coefficients :

$$\mu_p(x) = \sum_{q=1}^{p} \lambda_q(x) \qquad (1 \leq p \leq l-1) \qquad (42)$$

These coefficients are represented on fig. 2. The abscise values have been shifted by $(l-1)/2$, so that the origin corresponds to the position of the effective edge of the fragment (i.e. the position of the edge obtained when using n original cells $\mathcal{C}_0$ without partial charges). One can see that the renormalization of the charges is relatively small. Indeed, even in the case $l = 10$, this renormalization is weaker then 1% for charges at distances larger than $2u_0$, ($u_0 = a_0, b_0$ or c_0).

IV. OPTIMIZED METHOD

We first use the cells $\mathcal{C}_l$ to illustrate the convergence of the standard, real-space calculation of the potential established in section II. In order to observe the general behavior of the different methods, we chose the α quartz structure, that possesses a reasonable number of atoms per unit cell and not too many symmetries. A cell $\mathcal{C}_l$ is constructed for a fixed number of p. The cells are used to produce sets of charges of increasing size. The potential is calculated at the position of the twelve atoms of the central unit cell $\mathcal{C}_0$.

Fig. 3 a) represents the maximum of the error made on these potential values as a function of the width of the set of charges, and fig. 3 b) represents the maximum of the error made on the sixty six differences of potential. As expected the error decreases as a power function of the width D of the set of charges. It fully agrees with eq. 18 and 28. In particular, the fact that the cancellation of a momentum of odd order do not increase the convergence rate of the potential at a point, clearly appears. Similarly, the cancellation of even order momentum do not improve the convergence rate of the calculation of differences of potential.

One can see from the previous figures that this stan-

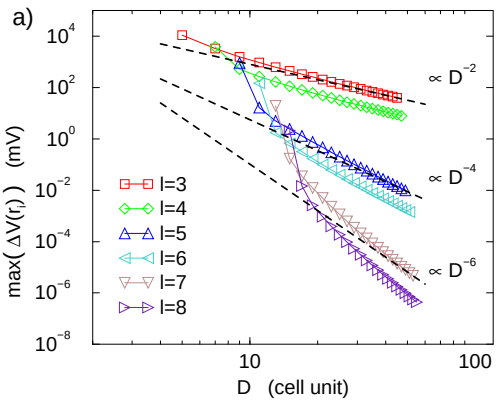

FIG. 3: (color online) a) Maximum of error made on the calculation of the potential at the position of the atoms of the central unit cell. $D = n' + 2l - 2$ is the width of the sets of charges in each crystallographic direction, where n' is the width of the central zone where the charges have their nominal values. l is the order of the first non zero momenta of the cell $\mathcal{C}_l$ used to construct the set of charges. b) Maximum of error made on the calculation of the difference of potential.

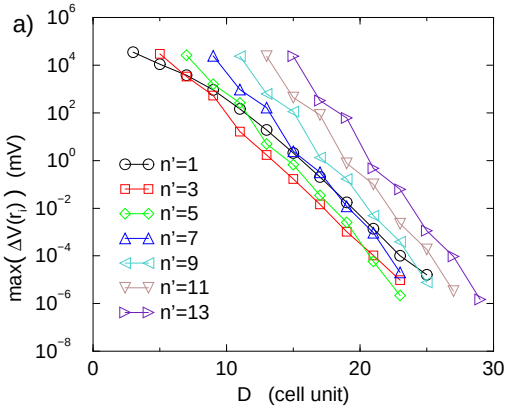

FIG. 4: (color online) a) Maximum of error made on the calculation of the potential at the position of the atoms of the central unit cell. The abscise corresponds to the width $D = n' + 2l - 2$ of the sets of charge in each crystallographic direction, where n' is the width of the central zone with nominal charge values. b) Maximum of error made on the calculation of the difference of potential.

dard approach is not the more efficient. Indeed the increase of the number of zero multipolar momenta clearly yield a faster convergence rate than the increase of the volume of the system for a fixed value of l. Let us therefore fix the width n' of the volume containing the nominal charge, and let l increase. The variation of the maximum error made on the potential and on the the potential differences are respectively represented on fig. 4 a) and 4 b). One sees that the present approach leads to an exponential convergence of the potential in both cases. The convergence is very fast, since an increase of the set of charges width by two unit cells results in a precision increase by a factor better than ~ 10. Increasing the number n' of central cells without partial charges has a small influence on the convergence speed. For $n' > 3$ the method even becomes less efficient since increasing n' increases the size of the total set of charges. The best convergence is obtained for $n' = 3$. It corresponds to the case where the cell in which the potential is calculated is surrounded by one shell of cells with the nominal charge values.

Finally we compare our method to the famous Ewald's method which mixes calculation in real space and reciprocal space. This method introduces Gaussian distribution of charge $exp(-\alpha^2 r^2)$, where the α coefficient can be adjusted. Increasing α coefficient increases the convergence rate of the real space sum, but slows down the sum in reciprocal space. A width of Gaussian proportional to the characteristic length of the unit cell, which corresponds to $\alpha_0 = \omega^{-1/3}$, is generally assumed to give a good compromise. We calculated the error made on the value of the potential using the Ewald's method for different values of α around α_0. The results are represented on figure 5, as well as the error of our method obtained for $n' = 3$. Figure 5 reports the error on the potential as a function of the number of construction cells used in the calculation. Let us point out that, while this variable is pertinent for the global convergence rate analysis, for each charge, the Ewald's method requires an error function evaluation resulting in a non negligible pre-factor, not present in our method and not taken into account in figure 5. One sees that the convergence rate of the

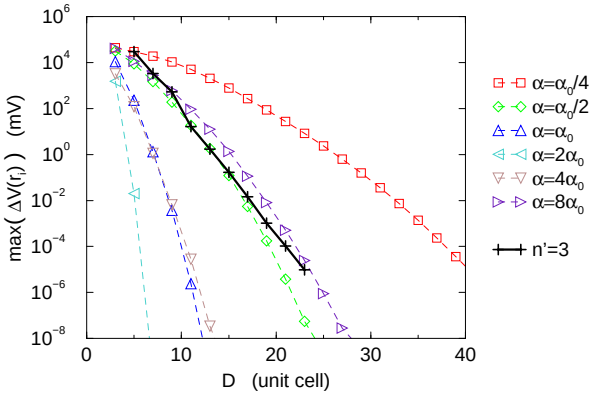

FIG. 5: (color online) Error on the Madelung's potential evaluation using the present method (bold black solid curve) and the Ewald's method with different parameters α (colored dashed curves).

present method is comparable with the Ewald's method. If one is only interested in the potential evaluation at a single point, the Ewald's method with an optimal α parameter is somewhat faster than the present one. One the other hand, once the renormalization have been computed, the value of the potential at any other point of the of the central area can be calculated with a similar precision at little cost. More important, properties using potential integrals or complex potential functions can be more easily evaluated since our method used only algebraic functions.

V. CONCLUSION

Number of authors have searched for a fast converging method for the evaluation of the electrostatic potential in real space. Similarly, many works where done yielding partial results on the convergence rate of such real series. The present work fills the gaps and proposes a general analysis of both the convergence of the potential at one point and of the convergence of differences of potential. Indeed, we gave a general and rigorous proof of the relation (claimed by other authors) between the power law convergence of the series and the number of zero multipolar momenta of the crystal construction cell.

Based on these convergence analyses we derived a general real space method with an exponential convergence rate, comparable with the Ewald's method. The exponential convergence is reached as a function of the number of canceled multipolar momenta in the *construction* cell. The crystal is indeed constructed using overlapping *construction* cells with renormalized charges. We derived a general analytical expression of the renormalization factors, for any given number of zero multipolar momenta.
